Abstract: Robotic-assisted thoracic segmentectomy is a minimally invasive option for the treatment of the resectable lung cancer. Its advantages over conventional video-assisted thoracic surgery include a clear and magnified three-dimensional operative field and the flexible multi-joint arms. This technical article presents a case from our center to share some surgical techniques for this procedure.

Keywords: Segmentectomy; robotic-assisted thoracic surgery

Clinical data

A 65-year-old woman was admitted because of pulmonary nodules for 1 month detected by computed tomography (CT). Chest CT (Figure 1) showed ground glass opacity (GGO) in the S^{1+2+3} segment of the left upper lobe. The patient’s complaints did not include chest tightness, shortness of breath, cough, expectoration, low fever, chills, night sweats or hoarseness. Cardiopulmonary function, blood gas analysis and laboratory tests were normal. There was no positive sign or supraclavicular lymph node enlargement in physical examination. She had no past medical history.

Operation steps

Anesthesia and body position

The patient received general anesthesia by double-lumen endotracheal intubation and was placed in the lateral decubitus position and in a jackknife position with single-lung (right) ventilation (Figure 2).

Ports

A 1.5-cm camera port (for a 12-mm trocar) was created in the 8th intercostal space (ICS) at the left mid axillary line, and three separate 1.0-cm working ports (for 8-mm trocars) were made in the 6th ICS (#1 arm) at the left anterior axillary line, the 8th ICS (#2 arm) at the left posterior axillary line, and the left 7th ICS (#3 arm), 2 cm from the spine. An auxiliary port (for a 12-mm trocar) was made in the 8th ICS near the costal arch (Figure 3).

Installation of the surgical arms

The robot patient cart was positioned above the operating table and then connected. The #1 arm was connected to a unipolar cautery hook and the #2 arm was connected with bipolar cautery forceps. An incision protector was used in the auxiliary port.

Surgical procedure

See Figures 4-18.

Postoperative condition

Postoperative treatments included anti-inflammatory and phlegm-resolving treatments. The thoracic drainage tube was withdrawn 2 days after surgery, and the patient...
was discharged 3 days after surgery. No complications were observed during hospitalization. Pathological diagnosis was atypical adenomatous hyperplasia (AAH) at local alveolar epithelium of the $S_{1-2+3}$ segment of the left upper lobe.

**Discussion**

The segmental dissection of the left upper lobe is a major challenge in robotic surgery because of the thin segmental vessels and bronchus. In addition, it is not easy to determine the segmental plane. The many arterial branches in the left upper lobe should be identified carefully when dissociating and pulling, especially the short branch $A_3$. For that reason, the surgeon should be familiar with the fine anatomy of the vessels and bronchus. The robot has a clear and magnified field of view and flexible arms, which make dissection and use of Endo-GIA stapler easier compared with the thoracoscope. The #3 arm can help the

surgeon to find the pulling location, which reduces the work of the assistant. In all surgeries, we dissect the hilum using a posterior approach and expose the pulmonary artery, which improves safety. We inject CO$_2$ before removing the specimen of lung lobe to form a closed space, which keeps the operation field clear (1-5).
