Clinical data

The patient was a 53-year-old woman with a history of dysphagia for 3 months without nausea, vomiting, hematemesis, or stomachache. A protruding mass was detected 25–30 cm from the incisors by gastroscopy. The pathological biopsy result was esophageal squamous cancer. The patient lost 5 kg without anorexia. A physical examination showed no positive sign, and results of preoperative biochemical tests were all normal. Enhanced computed tomography (CT) scan revealed a thickened upper esophagus wall and enlarged lymph node in the superior mediastinum (Figure 1). Informed consent for robotic-assisted thoracic lobectomy was obtained from patient before operation.

Operating steps

Anesthesia and position

After general anesthesia, the patient was placed in a left lateral decubitus position with left one-lung ventilation in thoracic part (Figure 2). Supine position with two-lung ventilation in the abdominal part (Figure 3).

Abdominal ports (Figure 4): the five-port method was used. The subumbilical port was used for observation (12-mm trocar), the #1 robotic arm was placed on the left anterior axillary line under the costal arch (8-mm trocar), the #2 robotic arm was placed on the right anterior axillary line at the umbilical level (8-mm trocar), and the manual operative port was placed on the right mid clavicular line at 3 cm under the costal arch (12-mm trocar). An auxiliary port was placed on the left anterior axillary line at the umbilical level (8-mm trocar).

Thoracic ports (Figure 5): the five-port method was used. The observation port was placed on the right anterior axillary line at the 5th intercostal space (12-mm trocar), the #1 robotic arm was placed on right posterior axillary line at the 3rd intercostal level (8-mm trocar), the #2 robotic arm was placed on the right posterior axillary line at 8th intercostal space (8-mm trocar), and the manual operative ports were placed on the right posterior axillary line at the 10th (5-mm trocar), and an auxiliary port were placed on the right anterior axillary line at 7th intercostal spaces (12-mm trocar).
Docking the robotic arms

The robotic arms were docked through the operation table overhead, the #1 robotic arm was connected to a bipolar electric coagulation forceps, and the #2 robotic arm was connected to a hook electrode. A lap-protector was used to avoid incision infection.

Surgical procedures

See Figures 6-23.

Postoperative results

The chest tube was removed on the second day postoperative day, and the patient was discharged on the sixth day postoperative day. No complications occurred during hospitalization. Pathologic diagnosis was esophageal squamous cancer (TNM stage was T3N0M0, stage IIA).

Comment

The first robotic-assisted minimally invasive esophagectomy (RAMIE) in the world was reported in 2003 by Dr. Horgan (1). Previously, research focused on RAMIE was limited because of the operative difficulties of minimally invasive esophagectomy, and the McKeown approach was the most widely adopted RAMIE approach. In 2010, Dr. Kim reported 21 cases of RAMIE to verify the feasibility and safety of the McKeown approach (2). In 2014, van der Sluis analyzed the clinical data of 108 patients who underwent RAMIE using the McKeown approach. The

results showed that in-hospital mortality was 5%, 5-year-survival was 42%, and 47.2% cases had local or systemic recurrences. In this case, to avoid potential local recurrence, we removed the tumor during the thoracic part of the operation and connected the stumps of the upper and lower esophagus by using ribbon gauze. We found that the three-dimensional vision and robotic arm provided great accessibility for the subtle manipulations, especially while dissecting lymph nodes around the recurrent laryngeal nerves. It was reported that RAMIE could reduce the

incidence of hoarseness (3) and provide satisfactory short-term outcomes (4). However, whether RAMIE can provide long-term benefits to patients with esophageal cancer needs further study.
